Category:Autodesk softwareElectronic device industry strives for increased speed, functionality and size reduction of their electronic products. The electronics industry has directed substantial effort toward improving of the electrical connection between an integrated circuit chip and the next level of packaging, commonly referred to as the substrate or carrier. The substrate may be a printed wiring board, a silicon or ceramic material, a tape or film, or a combination of such materials. It may also have extra functions, such as signal conditioning or testing. For effective interconnection, the substrate should be a good conductor and has a surface with suitable properties. Its electrical connections should be robust, reliable, and easily maintained. Packaging techniques which involve surrounding the chip with a mold compound tend to make use of a cheaper electrical conductor, such as an epoxy-based solder-based material, to form the interconnections. However, the mold compound is an electrical insulator, and the interconnections must be relatively thick to carry the full current from the chip to the substrate. It is desired to interconnect the substrate to the chip with many thin, parallel conductors to reduce the resistance and cross-talk between the connections, and this requires filling the space between the chip contacts. This becomes more difficult as the chip contacts themselves are placed closer together to reduce the device size. Typically, the chip and the substrate are formed using a semiconductor fabrication process. For example, the substrate is made as a silicon wafer, each chip is made on a wafer and placed on a wafer carrier, and the wafer carrier is placed in a mold where a layer of plastic is formed around the wafer to protect the wafer from damage while handling is performed and while the wafer is being placed in a package or bonded to a carrier. After removal from the mold, the wafer is diced into chips. At this stage, the chip can be electrically tested and connected to a substrate. The chip is then packaged for use. A variety of assembly techniques are used in making connections to the semiconductor chip. One example technique is called flip-chip bonding, or C4 technology. In flip-chip bonding, the active circuit surface of the semiconductor chip is provided with a set of solder bumps, and the substrate is provided with matching, typically smaller than the chip solder bumps, contacts. The chip is flipped over such that the chip active surface faces the substrate, and the chip solder bumps align with the substrate contacts. The assembly is then heated to form a reliable bond
